# **Evaluation of Foliar Fungicides** on Soybeans in Southeast Iowa

### **RFR-A1574**

Daren Mueller, assistant professor Jean Batzer, assistant scientist Yuba Kandel, assistant scientist Stith Wiggs, research associate Department of Plant Pathology and Microbiology

#### Introduction

Foliar fungicides were assessed on soybeans across seven Iowa State University research station locations including the Northwest Farm (Sutherland), Northern Farm (Kanawha), Northeast Farm (Nashua), Curtiss Farm (Ames), Armstrong Farm (Lewis), McNay Farm (Chariton), and Southeast Farm (Crawfordsville) (Figure 1).

## **Materials and Methods**

The experimental design at each location was a randomized complete block with four replications. Details on cultivar, planting date, population, pesticide applications, and harvest dates are listed in Table 1. Fungicides and insecticides (Table 2) were applied with a selfpropelled research sprayer at growth stage R3 (beginning pod) at all seven locations, unless otherwise noted. Disease was assessed when soybeans were at the R6 (full seed) growth stage. Septoria brown spot was assessed by measuring the height of the highest infected leaf at two sites/plot and dividing this by the canopy height and multiplying by 100. Other foliar diseases were assessed by estimating the percent leaf area blighted on 20 leaves in the upper canopy. Only diseases greater than 1 percent severity were analyzed and included in this report. Green stem disorder (GSD) notes were taken once soybeans were at growth stage R8 (full maturity). Total seed weight/plot and moisture were measured with a 2009 Almaco SPC20 research plot combine.

Seed weight was adjusted to 13 percent moisture and yield was calculated.

#### **Results and Discussion**

The 2015 growing season had timely rains throughout the summer, including August, a crucial time for disease development on soybeans.

There were three fungal diseases with measureable levels of disease at one or more locations; Septoria brown spot, white mold, and Cercospora leaf blight. Soybean vein necrosis virus, Pyllosticta leaf spot, downy mildew, and frogeye leaf spot were identified at several locations but at very low levels. GSD notes were taken at all the locations. GSD was greater in 2014, but was inconsistent across locations. Fungicides slightly increased GSD compared with the untreated control, but no differences between products were observed.

Yields averaged between 62.5–83.7 bushels/acre, depending on location. Yields for the Southeast Research Farm are shown in Table 3. Yield responses to fungicide were minimal at all locations. There were both negative and positive responses to various treatments at some locations, but nothing consistent was observed over the seven locations. The average yield response for all R3 applied fungicides across all locations was 2.1 bushels/acre.

For the most part, fungicides had minimal or no effect on seed moisture or green stem disorder. This information is from a single year (2015) and is not meant to be representative of pesticide performance every year. Additional research and analyses are required to fully understand the effect of these pesticides on soybean in Iowa.

## Acknowledgements

This research was partially funded by Iowa Soybean Association checkoff dollars. The

authors would like to thank all the research farm staff for their help during the growing season to successfully conduct these trials.
